ABSTRACT: The photosystem I (PSI) protein complex is known to enhance bioelectrode performance for many liquid-based photoelectrochemical cells. A hydrogel as electrolyte media allows for simpler fabrication of more robust and practical solar cells in comparison to liquid-based devices. This paper reports a natural, gel-based dye-sensitized solar cell that integrates PSI to improve device efficiency. TiO$_2$-coated FTO slides, dyed by blackberry anthocyanin, act as a photoanode, while a film of PSI deposited onto copper comprises the photocathode. Ascorbic acid (AscH) and 2,6-dichlorophenolindophenol (DCPIP) are the redox mediator couple inside an agarose hydrogel, enabling PSI to produce excess oxidized species near the cathode to improve device performance. A comparison of performance at low pH and neutral pH was performed to test the pH-dependent properties of the AscH/DCPIP couple. Devices at neutral pH performed better than those at lower pH. The PSI film enhanced photovoltage by 75 mV to a total photovoltage of 0.45 V per device and provided a mediator concentration-dependent photocurrent enhancement over non-PSI devices, reaching an instantaneous power conversion efficiency of 0.30% compared to 0.18% without PSI, a 1.67-fold increase. At steady state, power conversion efficiencies for devices with and without PSI were 0.042 and 0.028%, respectively.

KEYWORDS: Photosystem I, solar cell, biophotovoltaics, dye-sensitized solar cells, electrochemistry, renewable, gel electrolyte, two-electrode

INTRODUCTION

The current state of solar energy conversion relies on devices with nonrenewable components, unsustainable processing, and unfavorable cost-to-efficiency ratios.\(^1\)\(^,\)\(^2\) To resolve these issues, biological materials that efficiently harness the power of the sun are being explored.\(^3\) Photoactive biological materials mass produced by nature are prospective components to drive down the cost and achieve near-perfect internal quantum efficiency.\(^4\)

PSI is known to improve the photoelectrochemical performance of many electrode materials under various conditions.\(^5\)\(^–\)\(^11\)Photoelectrochemical investigations of PSI have commonly used a three-electrode liquid cell to enable a focused study of the photoelectrochemical interface between PSI and a single electrode.\(^10\)\(^,\)\(^12\)\(^,\)\(^13\) In contrast, fewer researchers have reported the use of PSI in a two-electrode solar cell,\(^13\)\(^–\)\(^20\) and most of these include solid-state devices.\(^14\)\(^–\)\(^16\)\(^,\)\(^19\)\(^,\)\(^20\) Solid-state devices with PSI depend on direct electron transfer from electrodes or conducting materials to and from the P$_{700}$ and F$_{b}$ sites, which complicates device fabrication in comparison to devices dependent on mediated electron transfer (MET). Alternatively, liquid cells rely on MET, in which redox reactions occur throughout a protein film as reactants freely diffuse to the electrodes.\(^21\)

The dye-sensitized solar cell (DSSC) is a promising, liquid-based technology that is able to mimic photosynthesis and produce robust solar conversion efficiencies.\(^22\) Traditionally, high-performing DSSCs’s rely on an iodide/triiodide (I$^-$/I$_3^-$) mediator in acetonitrile with a ruthenium-based dye to sensitize the electrode.\(^13\) Issues with the traditional high-performance devices are the toxicity and high volatility of organic solvents as well as the high cost for the ruthenium-based dyes.\(^22\)\(^,\)\(^23\) PSI has been explored as a way to boost DSSC performance and, in some cases, as a way to improve renewability and cost-effectiveness. PSI has provided improvement when used as a dye-sensitizer\(^5\)\(^,\)\(^24\) and as a redox film on a blackberry dye-sensitized TiO$_2$ electrode.\(^25\) In these investigations, PSI was deposited onto TiO$_2$ to boost anode
performance, but using PSI to boost cathode performance while being paired with a dye-sensitized anode has not been previously explored.

Along with three-electrode investigations, PSI performance has been measured in two-electrode photoelectrochemical devices or “wet” cells. PSI films have been used to form a photobioelectrode in a device with electrolyte mediators such as Cyt c$_{553}$ and the ascorbic acid (AscH)/2,6-dichlorophenolindophenol (DCPIP) couple. Additionally, PSI on gold improved performance with a copper/ITO counter electrode in an AscH/DCPIP mediator. The cell showed consistent performance over 280 days but did not reach above 0.001% external efficiency and required refilling of the liquid electrolyte. PSI also enhanced a traditional I$_x$/I$_3$ DSSC with a Pt/FTO counter electrode, boosting efficiencies from 0.24 to 0.47% when PSI was used as a macromolecular dye in TiO$_2$.\(^5\)

Despite these successes, liquids are disadvantageous as electrolyte media in photovoltaic systems because of portability issues and continual maintenance resulting from leakage, evaporation, or sealant failure.\(^28\) A quasi-solid-state gel medium negates the limitations prevalent in liquid cells while also providing similar transport capabilities for redox species. A gel analogue of a DSSC with an I$_x$/I$_3$ mediator exhibited improved photocurrent stability after 125 days of operation versus an equivalent liquid cell.\(^29\) These advantages allow for the minimization of evaporation and enhanced portability while still harnessing MET.

**Device Design.** The goal for this investigation is to design a low-cost, renewable photovoltaic device that integrates a DSSC electrode with a gel-based medium and a PSI-coated cathode to elevate the performance of the cell, as measured via the short circuit current, open circuit photovoltage, and power output. Figure 1 shows a schematic of the gel-based biohybrid solar cell. The device utilizes an FTO-coated glass slide as a transparent current collector upon which the TiO$_2$ film is spin-coated, annealed, and loaded with anthocyanin dye. The gel media are 0.5% wt agarose hydrogel with a supporting electrolyte and an AscH/DCPIP mediator.

Aagarose is a naturally derived polysaccharide that is a principal component of agar, a gel commonly used for gel electrophoresis. Aagarose has been used in DSSCs and has shown performance enhancement over equivalent liquid cells.\(^30,31\) Aagarose can form a polymer matrix in an aqueous solution while maintaining similar ionic conductivity and negating environmental hazards introduced in other types of media.\(^32\) The use of agarose here allows for simple addition of redox mediators to customize the internal environment of the cell. Badura et al. confined PSI in a thin cross-linked Os-based redox hydrogel film of allylamine and vinylimidazole on a gold electrode in an aqueous three-electrode system purged with O$_2$ and a methyl viologen (MV) mediator to improve the performance of immobilized PSI.\(^32\) The success with the redox hydrogel system proves that PSI can function well in a gel, but the use of an organic chemical for the media, a precious metal electrode, and a toxic mediator suggest challenges in renewable scale-up.

PSI has been shown to increase photovoltage from 220 mV to over 500 mV when deposited atop a TiO$_2$ anode in a three-electrode cell using a [Fe(CN)$_6$]$^{4-/3-}$ mediator couple. The improvement was attributed to PSI reducing Fe(CN)$_6$ to oxidize Fe(CN)$_6$ to create a higher concentration of the reduced species near the mesoporous anode, which effectively reduces charge recombination.\(^25\) PSI is also known to produce the opposite kinetic asymmetry when exposed to the natural mediator couple AscH/DCPIP by more rapidly producing the oxidized form of DCPIP.\(^33\) This asymmetry implies that the oxidized form of DCPIP would accumulate within the vicinity of the PSI/electrode interface, benefitting cathode performance. The opposite kinetic asymmetry for the [Fe(CN)$_6$]$^{3-/2-}$ and AscH/DCPIP mediator couples stems from the half-wave potentials (E$_{1/2}$) being closer to either the reduction potential for the F$_B$ or P$_{700}$ reaction sites.

For this investigation, three mediator systems—AscH/DCPIP, MV, and [Fe(CN)$_6$]$^{4-/3-}$—were assessed via photocurrent-voltage (PCV) measurements. PSI is known to react with the oxidized form of DCPIP and quickly accept electrons from the F$_B$ site of PSI, creating an excess of oxidized species to reduce the cathode in a three-electrode cell.\(^33\) MV is an oxygen scavenger and can rapidly accept electrons from the F$_B$ site of PSI, creating an excess of reduced species near the cathode, which reduced the performance of this device. In the case of [Fe(CN)$_6$]$^{3-/2-}$, Fe(CN)$_6$ is a slow donor to P$_{700}$ while Fe(CN)$_6$ can quickly accept electrons from F$_B$, leading to an excess of reduced species.\(^37\) In contrast to the reactions of MV and [Fe(CN)$_6$]$^{3-/2-}$ with PSI, the AscH/DCPIP mediator system is known to rapidly reduce P$_{700}$, causing an excess of oxidized species in solution.\(^33\) The AscH/DCPIP couple enhances current compared to the other mediators when PSI is deposited onto the cathode.\(^31\) Some photocurrent is present in the supporting electrolyte (KCl) control. This photocurrent is attributed to water and oxygen reacting within the system, but this contribution to current is small (<5 mA/cm$^2$), in comparison to the overall current with AscH/DCPIP.\(^38\)

AscH, commonly known as vitamin C, is an abundant, nontoxic molecule that protects PSI from harmful reactive oxygen species in vivo\(^39,40\) while DCPIP is a natural, nontoxic...
redox dye commonly used as a Hill reagent. Together, they are an efficient redox couple when paired with PSI.\(^4\) The reaction between AsCH and DCPIP is a catalytic electron transfer/homogenous chemical (EC\(^+\)) coupled reaction that catalytically generates reduced species.\(^4\) Having an excess of AsCH serves to increase the concentration of DCPIPH\(_2\) species in the cell by continually reducing DCPIP that is not reacted at the cathode. A schematic of the AsCH/DCPIP mediator system with PSI is shown in Figure S2.\(^3\) As reported herein, PSI can increase photocurrent at low mediator concentrations by converting the DCPIPH\(_2\) back to DCPIP near the cathode, yielding a higher rate of reduction and increasing the performance of the cell. The reaction kinetics for the AsCH/DCPIP reaction mechanism are pH dependent, prompting a comparison of cell performance at different pH values.\(^3\)

The placement of PSI on either the cathode or the anode was examined, with the observation that depositing a 4 μm thick, randomly oriented PSI film (thickness confirmed by profilometry, Figure S3) on the cathode provided enhancement while placing the film on the anode showed no improvement. PM-IRRAS spectra (Figure S4) were collected to verify the deposition of PSI onto the copper cathode. The IR spectra of a 4 μm thick PSI film show the presence of the characteristic Amide I and Amide II peaks at 1662 and 1545 cm\(^{-1}\), respectively.\(^4\) These results are consistent with the deposition of structurally intact PSI films on the copper cathode.

Copper was chosen as a suitable, inexpensive cathode because it has inherent energetic synergy with PSI and a substantial potential difference with the conduction band of TiO\(_2\) (0.34 and −0.30 V vs SHE).\(^3\) In nature, the oxidizing end of the PSI, the P\(_{700}\) site, accepts electrons from the copper-containing protein plastocyanin. TiO\(_2\) was selected as the semiconductor anode because it has a favorable energy band alignment with PSI and copper,\(^5\) it absorbs UV light well, and it can be deposited as mesoporous thin films that can be sensitized with dyes to enhance light absorbance in the visible spectrum.\(^6\) Anthocyanin (AC), a naturally occurring dye derived from blackberries, is used to sensitize TiO\(_2\) here because it absorbs light in the 500−650 nm wavelength range, complementing the absorbance of both TiO\(_2\) and PSI. PSI absorbs strongly in 400−500 nm and 650−700 nm wavelengths of visible light while TiO\(_2\) absorbs strongly at <400 nm.\(^6\) The TiO\(_2\) and AC anodes on FTO allow light at wavelengths complementary to PSI to pass through. The extracted dye consists of approximately 90 wt % cyanidin-3-glucoside and 10 wt % cyanidin-3-glucosyl-malonate.\(^6\)

As dye-sensitized TiO\(_2\) is known to be a good photo-anode,\(^2,5,6,7,8\) we focus here on improving copper cathode performance. We hypothesize that by using the naturally occurring mediator couple AsCH/DCPIP, we can harness the kinetic asymmetry of PSI’s redox capabilities and increase photocurrent with a PSI multilayer film deposited on the cathode of a photovoltaic device. Combining these materials, we report a PSI-derived natural DSSC, and we investigate the effect of PSI film thickness, pH, and mediator concentration on the performance of the cell.

**RESULTS AND DISCUSSION**

**Device Performance.** The effect of PSI on cell photovoltage and photocurrent over a range of mediator concentrations was examined. Additionally, devices were tested at two different pH ranges: low (2.5−3.5) and neutral (6.5−7.5). The pH-dependent mole fraction of the oxidized forms of DCPIP, as described by the Henderson–Hasselbach equation, with \(pK_a\)’s of 0.5 and 5.6 is shown in Figure 2, denoted as DH\(_2^+\), DH\(_-\), and D\(_-\).\(^4\) At the lower pH range, DH is the dominant oxidized form while at neutral pH, D\(_-\) is the dominant form, and these forms behave differently in cyclic voltammetry (Figure S5). A similar trend in activity versus pH was also observed by Petrova et al.\(^4\) Additionally, D\(_-\) reacts with AsCH at a kinetic rate that is 2 orders of magnitude slower than that for DH with AsCH.\(^4\) The overall reduction of the oxidized forms of DCPIP to DCPIPH\(_2\) occurs at all pH values, but the rate of reduction is pH dependent.\(^4\)

An advantage of a two-electrode device is that it enables the measurement of the photovoltage produced across the cell instead of examining the potential of only the working electrode that constrains three-electrode experiments. Figure 3a shows the photovoltage generated by the devices at all concentrations and each pH range. For a Nernstian equilibrium process, the potential of an electrode is dependent on the ratio of the concentration of oxidized to reduced species near the electrode and is therefore independent of bulk concentration as shown in the Nernst Equation:

\[
E(t) = E_0 + \frac{RT}{nF} \ln \frac{C_{O}(0,t)}{C_{R}(0,t)}
\]

(1)

Devices without PSI produce photovoltages of 0.35 and 0.37 V at low pH and neutral pH values, respectively, while the addition of a PSI film increases the photovoltage at each pH range. We expect that the faster reaction between PSI’s P\(_{700}\)\(^+\) and DCPIPH\(_2\) versus that between F\(_{B}\)\(^-\) and DCPIP generates higher concentrations of oxidized species near the cathode, increasing the ratio of oxidized to reduced species and, therefore, making the Nernstian potential at the cathode more positive. Consistent with this reasoning, the photopotential...
increases in the presence of PSI, raising the total photovoltage of the cell by 0.05 to 0.41 V, a 7-fold increase in the ratio of oxidized to reduced species for the devices measured at lower pH, and by 0.07 to 0.45 V, an 18.5-fold increase in the ratio for the devices measured at neutral pH. These large increases in the ratio of species are possible because of the ultralow concentration of oxidized species in the AscH/DCPIP system prior to light exposure and the localization of PSI on the cathode. The greater increase in photovoltage for the devices at neutral pH is attributed to D− reacting slower with AscH than DH does at low pH, so the oxidized species generated by PSI are not consumed as rapidly, increasing the ratio of oxidized to reduced species at the cathode.43,45

Devices at low pH were linked in series to increase the total photovoltage (Figure 3b). The PSI-integrated devices exhibit a linear increase in photovoltage of up to 2.1 V for five devices in series as compared to 1.5 V for the devices without PSI. The photovoltage enhancement with PSI becomes important in scaling-up device fabrication because fewer materials would be needed.

PCA was used to determine how the PSI film affects the photocurrent generation at various AscH/DCPIP mediator concentrations. Figure 4 shows representative PCA curves for devices at low and neutral pH values with and without a PSI multilayer. Values were measured after 30 s of illumination for each device. For each data point, the initial ratio of AscH to DCPIP concentrations is 20:1. The instantaneous maximum power output and efficiencies of 0.042 and 0.028%, respectively, for the devices with and without PSI were produced to measure the power output with and without PSI (Figure 6a). The power curves were obtained by taking the average of power curves of devices at neutral pH were produced to yield accurate power performance (Figure 6b). PSI film on the cathode. At neutral pH, the presence of a PSI film contributes a 18−49% enhancement to photocurrent at intermediate concentrations but yields statistically similar photocurrents at high concentrations. Devices containing PSI at low pH and ranging from 2 to 20 mM AscH all showed improvements over the non-PSI devices. At 60 mM, the performance was similar, but at higher concentrations, the photocurrent density was well below that of the non-PSI devices. In all cases, photovoltage was still enhanced by 50−75 mV with PSI.

As the mediator concentration increases, the finite number of PSI reaction sites effectively becomes the limiting reagent in the production of O2, and thus, the photocurrent in the presence of PSI begins to plateau. Saturation of PSI sites via Michaelis–Menten processes at high mediator concentration has also been attributed to such plateaus.44,49 At low pH values, the devices with the PSI plateaus near 90 μA/cm2 at a concentration of 20 mM AscH and above while the neutral pH devices appear to begin plateauing above 20 mM AscH at a value ~200 μA/cm2. The difference in the plateaus with pH is attributed to the slower reaction of D− with AscH that yields higher concentration of oxidized species near the cathode, in addition to the increased electrochemical activity of D−.

The devices at neutral pH outperformed those at low pH, so power curves of devices at neutral pH were produced to measure the power output with and without PSI (Figure 6a). The power curves were obtained by taking the average of j−V curves done at forward and reverse scan directions to find the voltage where maximum power occurs. The forward and reverse scans (Figure 6b) differ because of an imbalance of charge extraction at the electrodes, whereas the average is more representative of actual device performance.50 Then, a steady-state power value was determined by measuring power output under illumination while devices were biased at the maximum power voltages until the steady state was reached to yield accurate power performance (Figure 6a). Devices at 20 mM AscH:1 mM DCPIP with and without PSI showed a maximum power output of 0.033 and 0.023 mW/cm2 and power conversion efficiencies of 0.042 and 0.028%, respectively. Table 1 shows the characteristic parameters for the j−V curves obtained from forward and reverse scans as well as the average values. Instantaneous power outputs were also measured by measuring a reverse-scan j−V curve at 10 V/s. The instantaneous maximum power output and efficiencies
with and without PSI were 0.24 and 0.14 mW/cm² and 0.30 and 0.18%, respectively (Figure S7).

To confirm that the decreased performance of the devices at low pH was because of pH and not the supporting electrolyte, replicate devices at low pH were fabricated using sodium nitrate as the supporting electrolyte, and the performance was the same as those in KCl. Additionally, devices at neutral pH with a KCl supporting electrolyte were tested and performed similarly to those with phosphate electrolyte. Phosphate is the preferred supporting electrolyte because it is stable, acts as a buffer around neutral pH values, and is not corrosive toward the copper cathode.

The presence of the relatively thick, 4 μm PSI film raised concern that a barrier effect might cause changes in performance. To confirm that the redox capabilities of PSI were causing the enhancements, devices with varying film thicknesses were fabricated by diluting the initial PSI suspension (Figure 7). Additionally, devices at low pH with a 4 μm film of deactivated PSI (thermally deactivated by boiling for 2 min) were also made to test the barrier properties of the PSI film. PSI multilayer films increased device performance with an increase in the thickness of the protein film by multiple deposition steps up to 2.5 μm because of the availability of more active sites in the protein film for the conversion of mediator. Here, the performance continues to increase with thickness, but beyond a thickness of 2 μm, the rate of increase slows, likely caused by the film becoming thick enough that light is unable to penetrate completely through it. Additionally, the device with the deactivated 4 μm thick protein film yields the same photocurrent density and photovoltage as the devices without PSI, indicating that the performance enhancements provided by PSI are not dictated by barrier or partitioning effects. This conclusion is also confirmed by electrochemical impedance spectroscopy (EIS) because the presence of a PSI film does not significantly affect transfer of ions to the electrode (Figure S8).

Collectively, these results support the conclusion that the observed enhancements in photocurrent and photovoltage are driven by PSI-mediator reactions.

**Model Analysis.** The reaction-diffusion system was modeled via Matlab using the pdepe and lsqcurvefit functions to solve the system of PDE’s and apply the method of least squares, respectively (see Supporting Information). The model was used to estimate photocurrent density after 30 s of illumination in devices at neutral pH with and without PSI. The resulting photocurrent densities were then normalized to squares, respectively (see Supporting Information). The model function was used to estimate photocurrent density after 30 s of illumination in devices at neutral pH with and without PSI. The resulting photocurrent densities were then normalized to the photocurrent density computed for a device without PSI at the same mediator concentration of 200 mM AscH to 10 mM DCPIP to compare the model to the experimental system (Figure 8).

Two of the parameters were unknown while formulating the model: the initial ratio of O to R concentrations ($C_0^O/C_0^R$) and the reaction rate constant for PSI ($k_{PSI}$). To find these parameters, the lsqcurvefit function was used to first match the model to experimental data without PSI to obtain the initial $C_0^O/C_0^R$ ratio. A value of $1.07 \times 10^{-4}$ represents an initial conversion of 99.99%, which is expected as the reaction of AscH with DCPIP is generally considered to approach completion.

A 99.99% conversion results in an ultralow initial concentration of O, allowing for PSI to provide a large (e.g., 18.5-fold) increase in the surface concentration ratios as seen by the photovoltage enhancements.

The value for the net rate of conversion of R to O by PSI ($k_{PSI}$) was determined by using lsqcurvefit to match the model to the experimental data with PSI, using the initial ratio of $C_0^O/C_0^R$ obtained by modeling the experimental data without PSI.

Figure 6. (a) Power curves of devices at neutral pH and a concentration of 20 mM AscH to 1 mM DCPIP. The resulting power curve represents an average of forward and reverse j–V scans at 1 V/s. Light intensity (80 mW/cm²) was used, and scans were run after 30 s of illumination. (b) Steady-state power generation of devices biased at the voltage where maximum power occurs.

**Figure 7.** Effect of PSI film thickness on device performance for 20 mM AscH:1 mM DCPIP at low pH. The deactivated data were collected by thermally denaturing PSI by boiling for 10 min before deposition. The photovoltage of the cell with the deactivated film of PSI is 0.35 V, which is the same as that of the cell without PSI (0.35 V).
The first-order rate constant was fit to be $1.98 \times 10^{-3}$ s$^{-1}$, showing that a positive net reaction rate for the production of O does result in improved photocurrent performance compared to non-PSI devices. Additionally, the model shows that if the net kinetic rate of conversion by PSI remains constant, a plateauing effect on photocurrent occurs as concentration increases, confirming that the reaction sites provided by PSI do indeed become a limiting reagent.

## Conclusions

A low-cost, renewable, and gel-based biophotovoltaic device was designed and easily fabricated in this study. The device uses abundant, environmentally friendly, and inexpensive materials, including PSI, copper, TiO$_2$, blackberry dye, AsH$_2$, DCPIP, and agarose. The use of an agarose hydrogel enables redox reactions to occur as in a liquid device while allowing simpler construction of a two-electrode device. Within the tested concentration range, photovoltage was independent of total mediator concentration, but devices at neutral pH outperformed those at lower pH because of the pH-dependent nature of the AsH$_2$/DCPIP couple. A $4 \mu$m thick PSI film increased photovoltage at low and neutral pH values by 50 and 75 mV, respectively, compared to devices without PSI to achieve values of up to 450 mV. Devices connected in series showed a linear increase in photovoltage with each device.

Photocurrent was dependent on mediator concentration, pH, and the presence of PSI. At both low and neutral pH values, PSI enhanced photocurrent at low to moderate mediator concentrations as compared to devices without PSI, but enhancement diminished as mediator concentration increased because of the limiting reaction capabilities of the PSI films. $j$–$V$ power curves obtained at neutral pH with 20 mM AsH$_2$ to 1 mM DCPIP concentration showed that PSI devices had a power conversion efficiency of 0.042% compared to 0.028% without PSI. Additionally, a numerical model was developed to examine the effect of PSI-mediated oxidation kinetics on photocurrent. The model is consistent with experiments, showing that the net reaction rate of the production of O species by PSI leads to photocurrent enhancements that are more dramatic at low and intermediate concentrations of mediator.

This investigation is the first to incorporate PSI in a two-electrode gel-based cell, showing that the asymmetric redox kinetics of the protein provides enhancement to both photocurrent and photovoltage when deposited on the cathode of a DSSC. The reported devices are environmentally friendly and made from easily sourced materials with low energy input compared to many other photovoltaic technologies.

## Experimental Section

### Materials

PSI used in this experiment was extracted from spinach purchased at a local market. Blackberries were also purchased from a local market. Redox mediators, (AsH$_2$ and DCPIP), Triton X-100 surfactant, hydroxypatite, TiO$_2$ paste (Dyesol 18NR-T), and supporting electrolytes (KCl and NaH$_2$PO$_4$) were all purchased from Millipore-Sigma. 10,000 MWCO dialysis tubing (Spectrapore) was purchased from VWR. Fluorine-doped tin-oxide (FTO) substrates (TEC15) were purchased from MTI Corporation. Minibinder clips (Staples) were used for device fabrication.

### PSI Extraction

PSI was extracted from commercially available spinach following steps described in previous work. In short, the spinach was deined, macerated, filtered, and then centrifuged at 8000g to isolate the thylakoid membranes. The supernatant was then mixed with a surfactant (Triton-X100) to lyse the membranes before the second centrifugation at 20,000g. A hydroxypatite column was used to isolate the PSI. The protein was dialyzed for 24 h using 10,000 MWCO dialysis tubing to remove salts and surfactants.

### FTO/TiO$_2$ Electrode Preparation and Dye Sensitization

FTO substrates were rinsed with ethanol and dried under a stream of nitrogen. The substrates were then treated with ozone plasma under vacuum for 15 min to create a hydrophobic surface. TiO$_2$ paste (Dyesol 18NR-T) was mixed in a 1:3 (v/v) ethanol solution and spin-coated onto FTO at 1500 rpm for 30 s. The films were then sintered at 500 °C in a muffle furnace for 30 min and cooled overnight.

To dye sensitize the TiO$_2$ substrate, 20 g of commercially available blackberries was crushed in a mortar by pestle and mixed with 20 mL of ethanol. Solids were filtered from the mixture, and the TiO$_2$ films were left in the dye solution for 12 h. The dyed films were rinsed in ethanol and dried under nitrogen before use.

### Gel Electrolyte Preparation

Aqueous-based electrolyte solutions of AsH$_2$ and DCPIP (in a ratio of 20 mM AsH$_2$ to 1 mM DCPIP) were used with AsH$_2$ concentrations ranging from 2 to 200 mM. For devices at lower pH, 100 mM KCl served as the supporting electrolyte while at neutral pH, 100 mM monobasic phosphate was the electrolyte. Agarose was added to each liquid electrolyte at 0.5 wt % and then stirred and heated to 120 °C. The media were cooled and formed an electrolyte gel.

### PSI Deposition and Device Fabrication

Copper tape was pressed onto FTO and used as the metal cathode. An insulating mask with a 0.28 cm$^2$ hole was placed over the copper, and a duplicate mask was placed on TiO$_2$, and 50 µL of 4 µM doped PSI was drop-cast onto the copper into the hole made by the mask. The PSI was then dried under vacuum for 30 min, leaving a multilayer film of randomly oriented PSI protein complexes. The thickness of the protein film was measured by profilometry (Dektak). The average thickness of the multilayer films was 4 µm, which is roughly 400 layers of protein assuming a height of 10 nm/layer based on the dimensions of PSI.

Agarose gel (100 µL) was placed within the opening of the mask on the metal substrate, with or without a PSI multilayer previously deposited. The FTO slide with the TiO$_2$ was then pressed on top of the cathode and bound with binder clips to form the device. The average distance between the cathode and electrode was measured to be 400 µm. PM-IRRAS performed with Bruker Tensor 27 FTIR at 1 cm$^{-1}$ resolution was used to confirm that PSI was deposited on the substrate.

### Photocurrent and Photovoltage Measurements

Electrochemical characterization was performed using a CH Instruments CH660a workstation equipped with a Faraday cage. Experiments were performed using the cathode as the working electrode and TiO$_2$-coated FTO as the anode and reference electrodes.

All photocurrent measurements were performed at a 0 V bias. Each sample was illuminated for 30 s using a 250 W cold light source (Leica KL 2500 LCD), which emitted a light intensity of 4470

![Figure 8. Comparison of model predictions (lines) for photocurrent density to experimental data (points) with PSI (filled points) and without PSI (open points) in devices at neutral pH. Values were normalized to the photocurrent density value of a device without PSI at a mediator concentration of 200 mM AsH$_2$ to 10 mM DCPIP.](https://doi.org/10.1021/acsabm.0c00446)
were normalized to the 0.28 cm² area made with the mask. The back and a Pt counter electrode in either 100 mM phosphate buffer or KCl. A scan rate of 0.1 V/s was used for all experiments.

j–V curves were produced via linear sweep voltammetry at a scan rate of 1 V/s. Scans were made in both forward and reverse directions. Scans were done after 30 s of illumination to reduce diffusion effects. Steady-state power output was determined by measuring photocurrent while the devices were biased at the voltage, where maximum power occurred on the j–V curves for each device.

PSI Model. We developed a simplified electrochemical reaction-diffusion model in Matlab. The model examined the change in concentration of oxidized and reduced species as well as photocurrent density during 30 s of illumination. Values after 30 s of illumination were taken as the pseudo-steady state for the device. Devices with and without a 4 μm-thick PSI film were modeled to investigate the function of PSI in the system at various mediator concentrations.

The assumptions made for this simplified model are that the cathode is limiting the current and therefore is where heterogeneous electrode kinetics are modeled, the initial ratio of O to R is the same with or without PSI for each initial total concentration, the diffusion coefficients for O and R are the same, the diffusion coefficients for DCPIP and AsCH in 0.5% agarose gel are 35% of their diffusion coefficients in liquid water, 0.77 × 10⁻⁹ and 0.87 × 10⁻⁹ m² s⁻¹, respectively, the charge transfer coefficient for the DCPIP mediator is 0.5, the potential of the rate-determining step for DCPIP is 0.217 V versus SHE, the exchange current is based on a 0.217 V versus SHE CV, the exchange current is based on a single-electron transfer as the rate-determining step of the two-electron DCPIP reaction, the PSI multilayer acts as redox film and does not partition concentrations, and AsCH does not react at the cathode. Values for variables and constants are shown in Table 2.

Bulk Gel. AsCH reactions occur homogeneously throughout the device with and without PSI. The equations are

\[ \frac{\partial C_{\text{O}}}{\partial t} = D_{\text{O}} \frac{\partial^2 C_{\text{O}}}{\partial x^2} - k_{\text{asc}} C_{\text{O}} C_{\text{asc}} \]  
\[ \frac{\partial C_{\text{R}}}{\partial t} = D_{\text{R}} \frac{\partial^2 C_{\text{R}}}{\partial x^2} + k_{\text{asc}} C_{\text{O}} C_{\text{asc}} \]  

where \( C(x,t) \) is the concentration of mediator, \( O = \text{oxidized} \) [DCPIP], \( R = \text{reduced} \) [DCPIP H₂], and AsCH = [AsH] at distance \( x \) and time \( t \), \( D \) is the diffusion coefficient of mediator \( i \), and \( k_{\text{asc}} \) is the reaction rate of AsCH with O. The equations are solved for \( x = 0 \) to \( x = 400 \mu m \) in the absence of a PSI film and for \( x = 4 \) to \( x = 400 \mu m \) with a PSI film, as eqs 5–7 below accounts for the reaction when PSI is present.

PSI Film. When a 4 μm thick film is present, PSI reacts with O and R, but the kinetic asymmetry of PSI produces more O species throughout the film. The equations are

\[ \frac{\partial C_{\text{O}}}{\partial t} = D_{\text{O}} \frac{\partial^2 C_{\text{O}}}{\partial x^2} + k_{\text{PSI}} C_{\text{R}} - k_{\text{asc}} C_{\text{O}} C_{\text{asc}} \]  
\[ \frac{\partial C_{\text{R}}}{\partial t} = D_{\text{R}} \frac{\partial^2 C_{\text{R}}}{\partial x^2} + k_{\text{PSI}} C_{\text{R}} + k_{\text{asc}} C_{\text{O}} C_{\text{asc}} \]  
\[ \frac{\partial C_{\text{asc}}}{\partial t} = D_{\text{asc}} \frac{\partial^2 C_{\text{asc}}}{\partial x^2} - k_{\text{asc}} C_{\text{O}} C_{\text{asc}} \]  

where \( k_{\text{PSI}} \) is the net reaction rate of PSI converting O to R. When a PSI film is present, the PSI film is treated as a homogenous redox active film. The unknown parameter \( k_{\text{PSI}} \) was fit to match the model with a PSI film being present. The value for \( k_{\text{PSI}} \) was found by using the method of least squares fitting to experimental data with PSI.

Initial and Boundary Conditions. O, R, and AsCH are all initially present, and the concentrations are assumed to be the same across the device resulting in the initial condition

\[ C(x, 0) = C_i \]  

where \( C_i(x,0) \) is the concentration at \( t = 0 \), and \( C_i \) is the initial concentration of \( i \). The initial ratio of O to R was found by using the method of least squares to fit the model to experimental data without PSI.

The fluxes of O and R at the electrodes are related to the current (\( j_{\text{cell}} \)) flowing through the cell by the following boundary conditions

\[ j_{\text{cell}} = nF D_{\text{O}} \frac{\partial C_{\text{O}}}{\partial x}\big|_{x=0} - j_{\text{cell}} = nF D_{\text{R}} \frac{\partial C_{\text{R}}}{\partial x}\big|_{x=400} \]  
\[ j_{\text{cell}} = nF D_{\text{R}} \frac{\partial C_{\text{R}}}{\partial x}\big|_{x=400} \]  

where \( n \) is the number of electrons transferred, and \( F \) is Faraday’s constant. For both O and R, the fluxes are opposite to each other at both boundaries to maintain charge balance within the cell.

AsCH is assumed to not be redox active at the electrodes leading to the boundary conditions

\[ 0 = \frac{\partial C_{\text{asc}}}{\partial x}\big|_{x=0} \quad 0 = \frac{\partial C_{\text{asc}}}{\partial x}\big|_{x=400} \]  

Heterogeneous Electrode Kinetics. At the cathode and anode, the surface concentrations of the species are related to current through Butler–Volmer electrode kinetics for a rate-determining electron process \( 2,3,7 \)

\[ j_{\text{cell}} = j_0 \times [e^{\alpha \eta} - e^{(1-a)\eta}] \]  
\[ \eta = E_{\text{copper}} - E_{\text{DCPIP}} + \frac{R T}{n F} \ln \frac{C_{\text{O}}(0, t)}{C_{\text{R}}(0, t)} \]  

where \( j_0 \) is the exchange current density, \( \alpha \) is the charge transfer coefficient, \( \eta \) is the overpotential, \( E_{\text{copper}} \) is the potential of the copper electrode, \( E_{\text{DCPIP}} \) is the \( E_{1/2} \) for DCPIP, and \( C_{\text{O}}(0, t) \) is the surface concentration of \( i \).
